**Interactions-think influential subgroups fooling with your results!!!!**

# Effects obscured by interaction

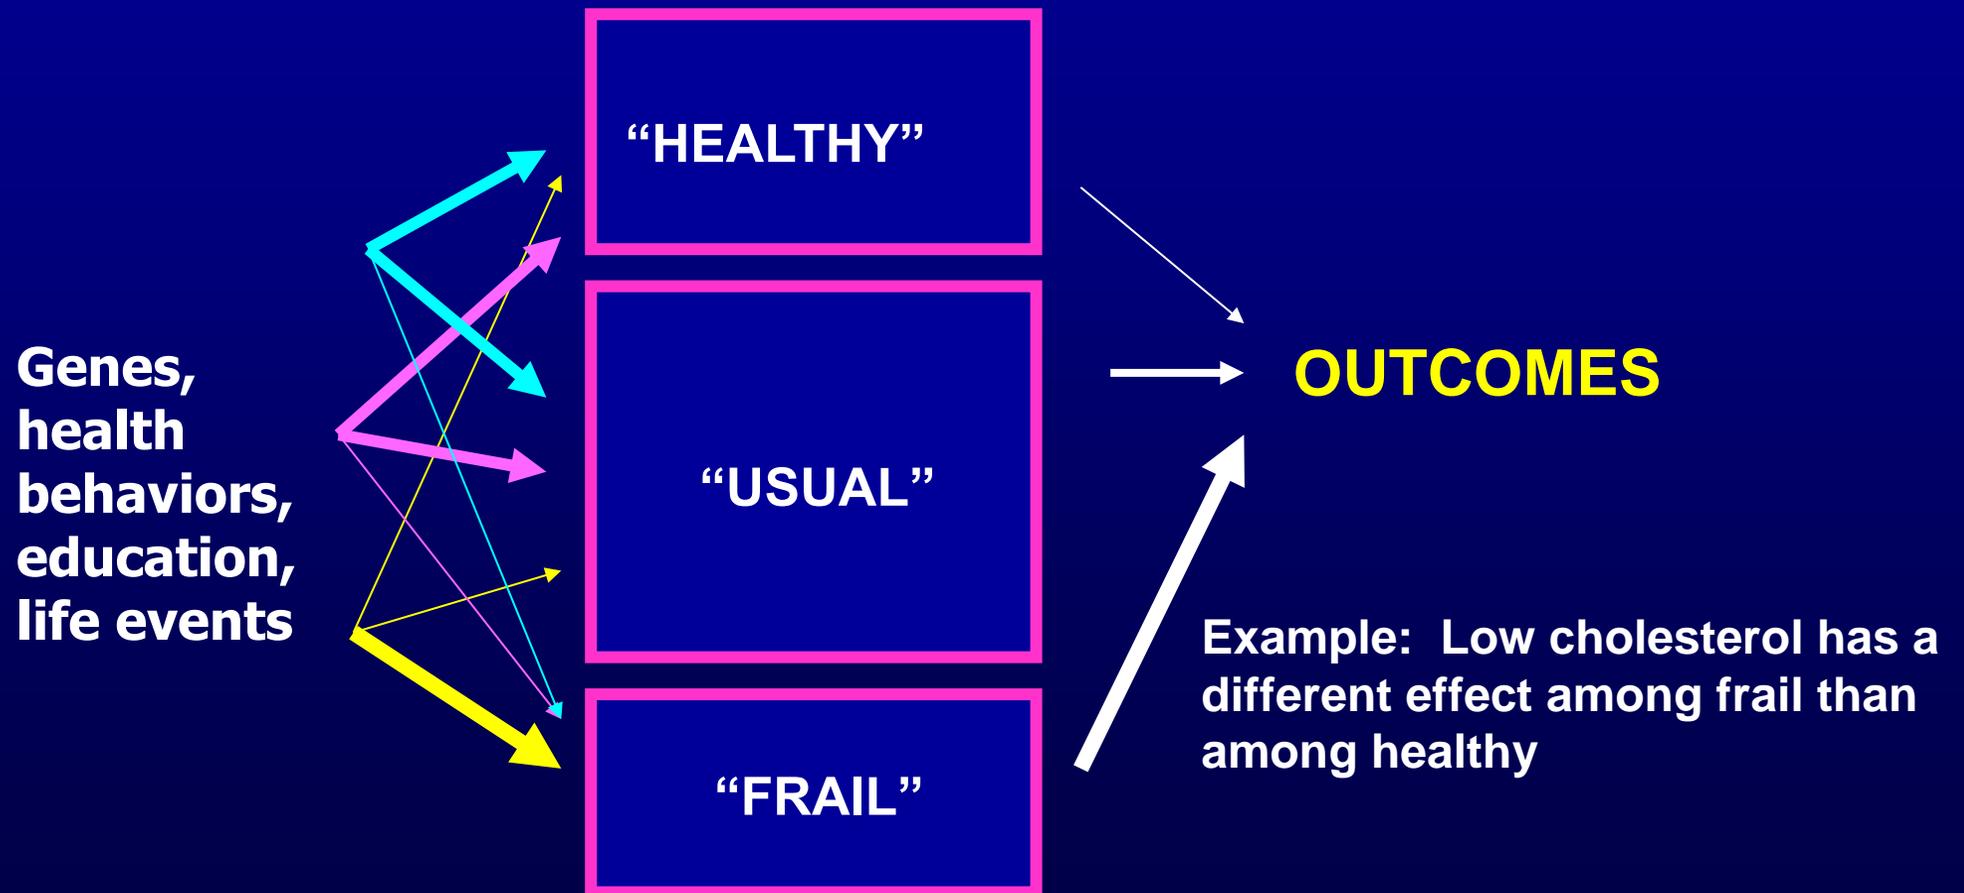

## **Does adjustment for confounders address this problem?**

**Interaction is all about stratification and occurs when an exposure has a different effect among different subgroups.**

**Confounding occurs when a factor is associated with both the exposure and the outcome but does not lie on the causative pathway.**

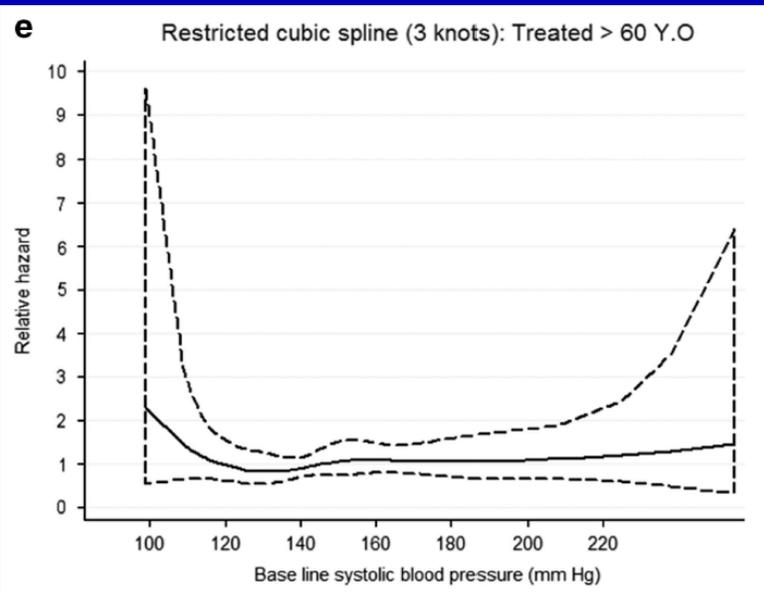

As populations age, there are more distinct differences between subgroups.

Interactions may become more common in old age. Lack of identification of these subgroups can lead to false results and inappropriate preventive strategies.

# Blood pressure example:

## Literature:

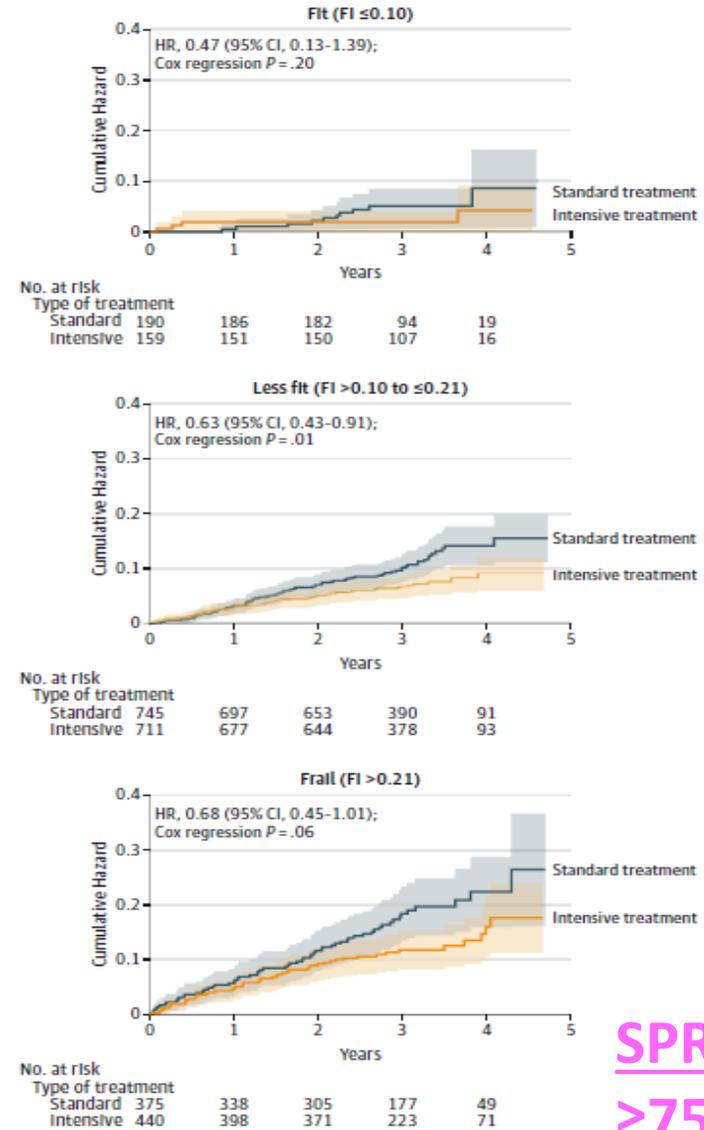

Journal of Human Hypertension (2017) 31, 415–421

## POLICY:

Concern that 2014 initiation/treatment recommendations differ for persons aged 60 or older

IS DIFFERENTIAL TREATMENT BY AGE OR FUNCTION WARRANTED?

Figure 2. Kaplan-Meier Curves for the Primary Cardiovascular Disease Outcome in Systolic Blood Pressure Intervention Trial (SPRINT) in Participants Aged 75 Years or Older by Baseline Frailty Status

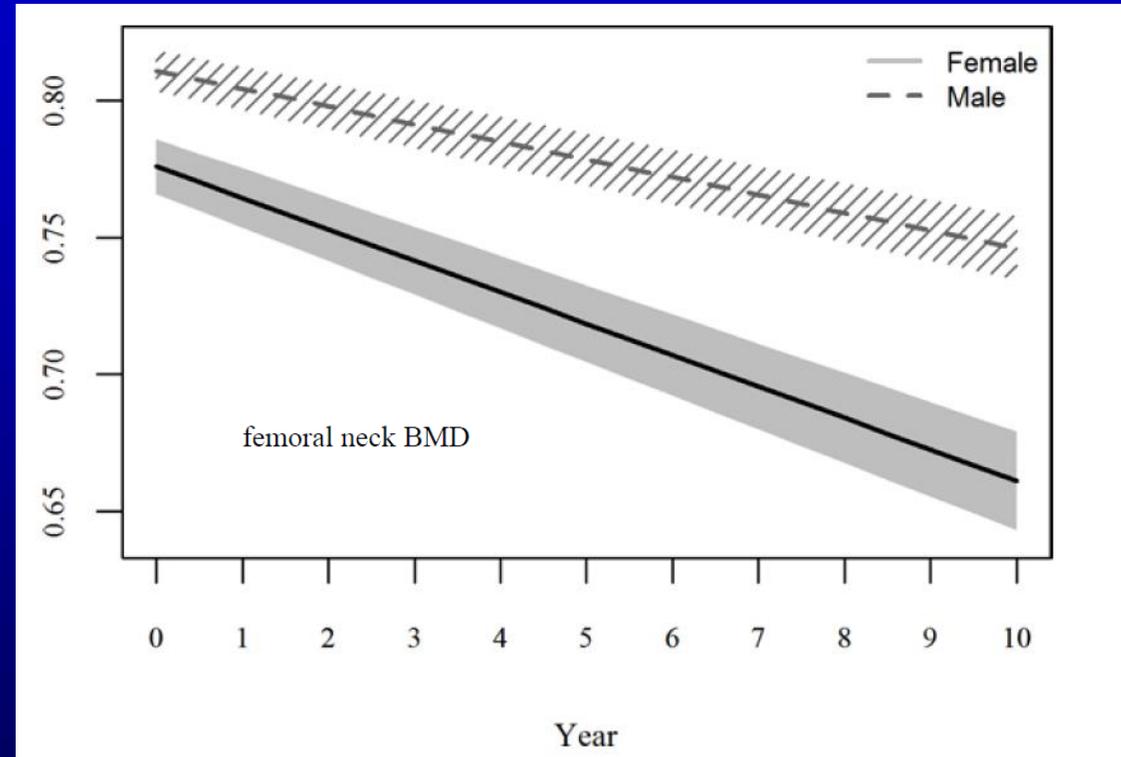

SPRINT TRIAL  
≥75 years old

Tinted regions indicate 95% confidence intervals; FI, 37-item frailty index; HR, hazard ratio. The primary cardiovascular disease outcome was a composite of nonfatal myocardial infarction, acute coronary syndrome not resulting in myocardial infarction, nonfatal stroke, nonfatal acute decompensated heart failure, and death from cardiovascular causes. JAMA. 2016;315(24):2673-2682. doi:10.1001/jama.2016.7050 Published online May 19, 2016.

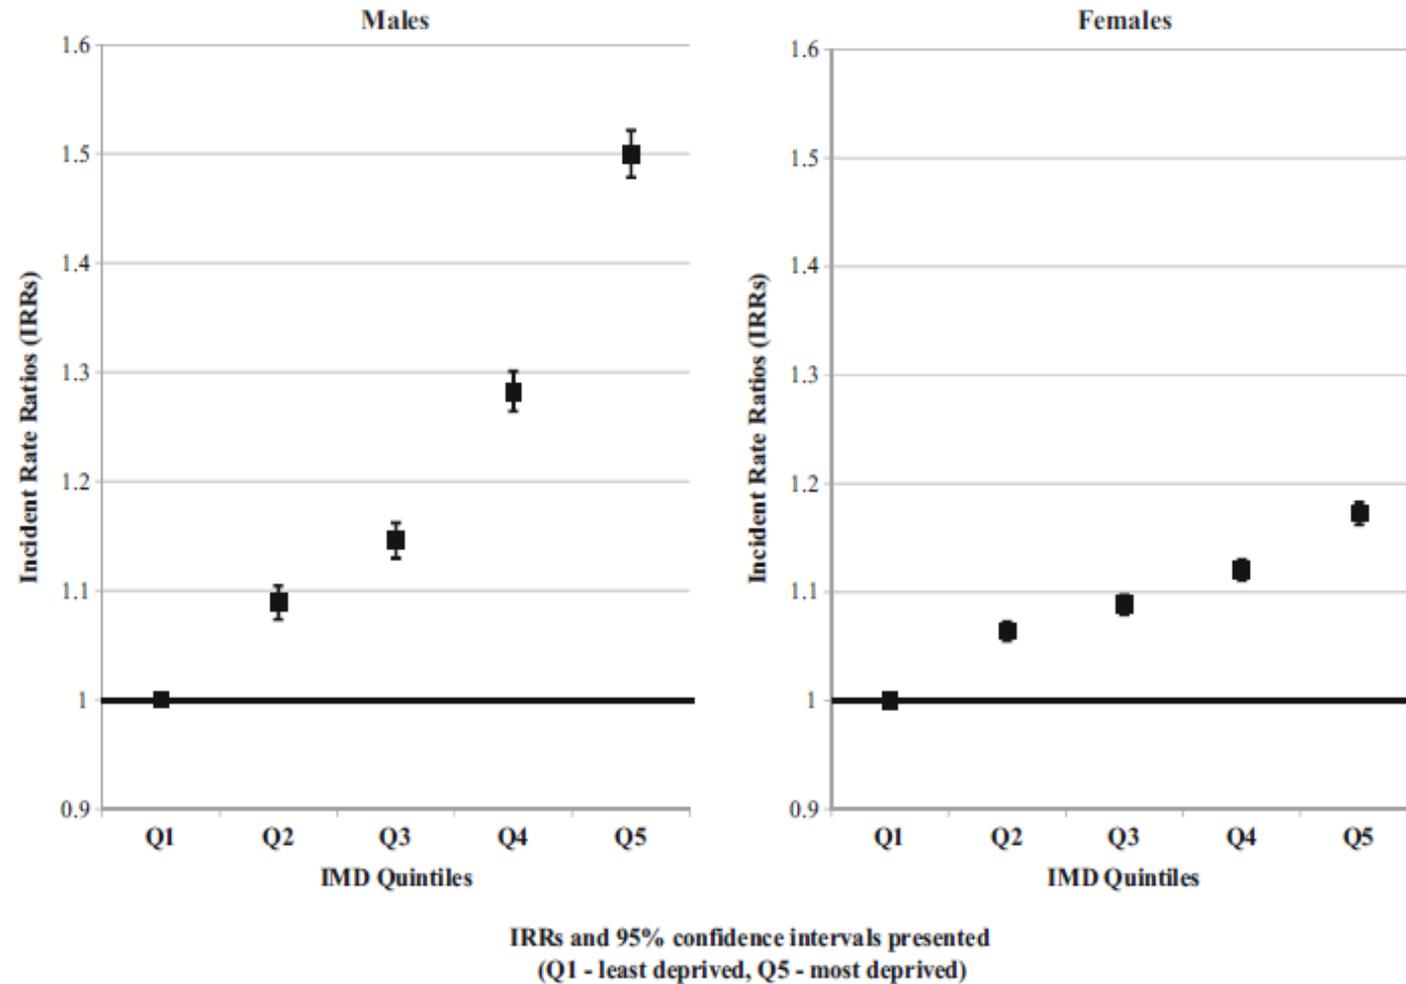

# Interaction by HIV status on gender for femoral neck BMD

Bone Mineral Density Declines Twice as Quickly Among HIV-Infected Women Compared to Men

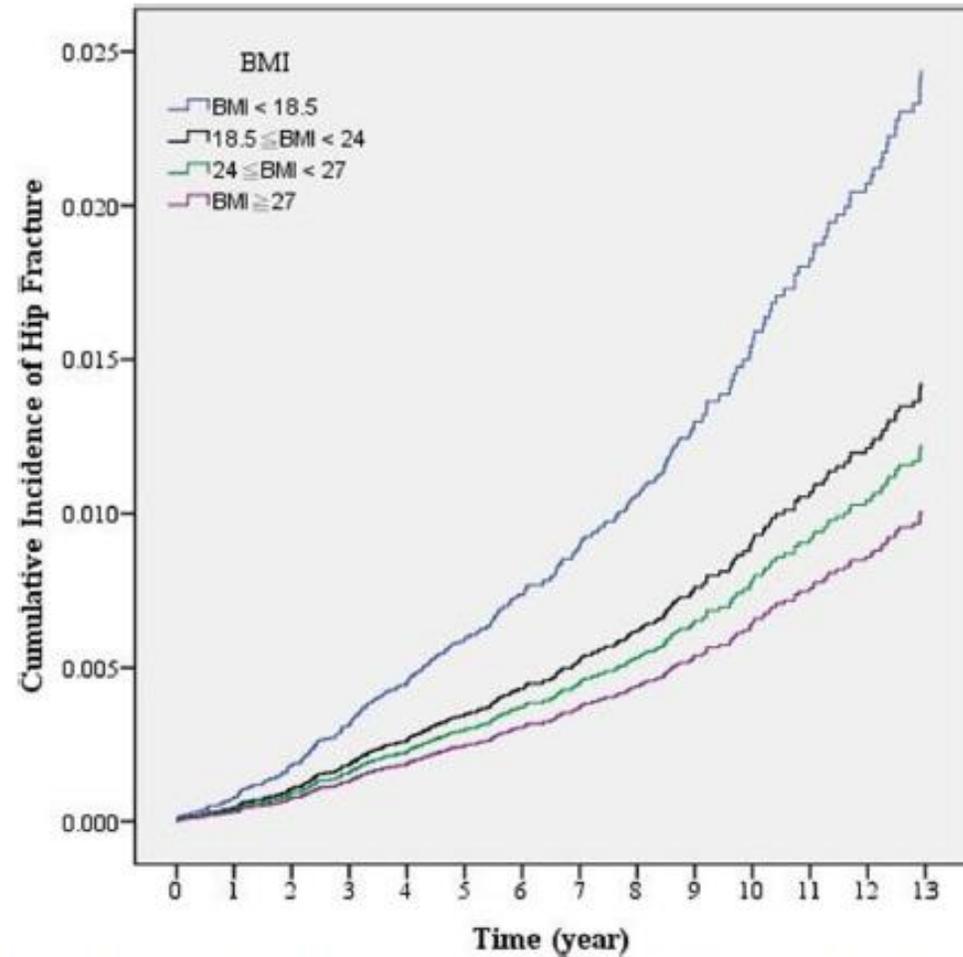

# Interaction by gender on SES deprivation for hip fracture

Fig. 1 Association between quintiles of deprivation and age-adjusted hip fracture incidence rates in men and women aged 50+ years residing in England, 2001–2014 (quintile 1 (Q1) (least deprived quintile)—reference category)

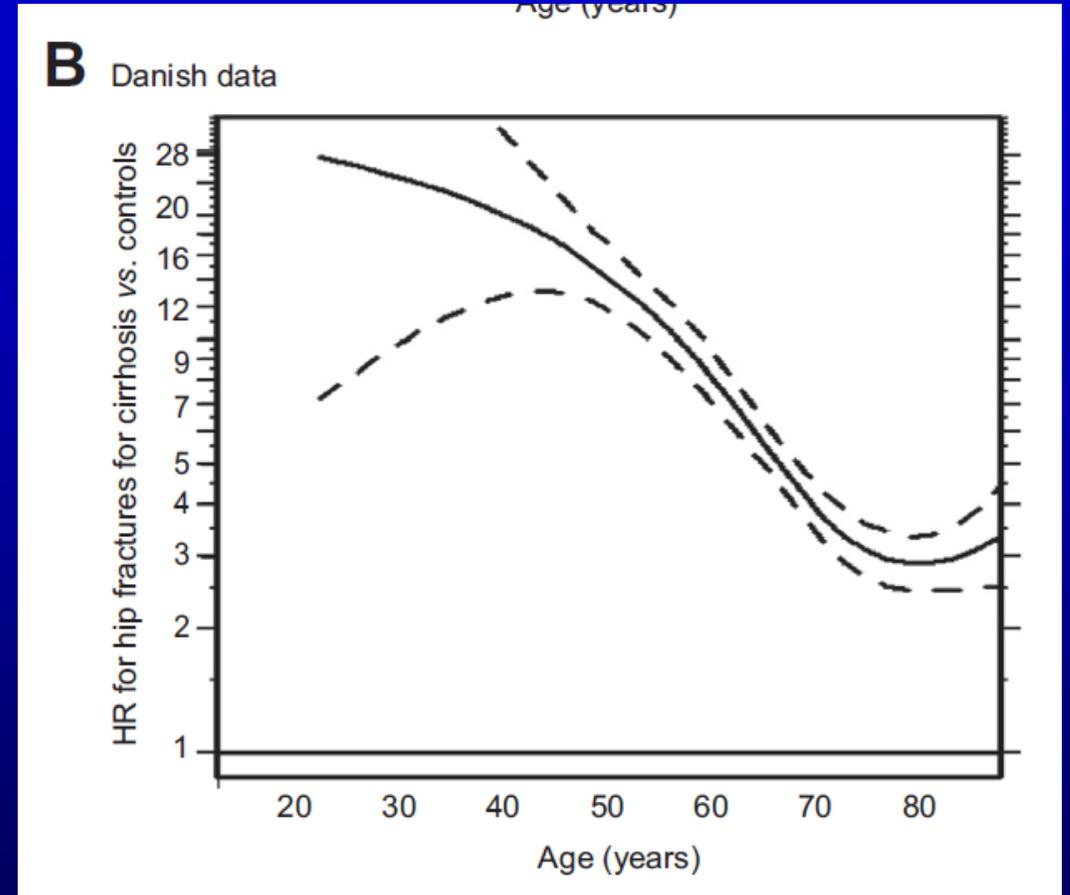

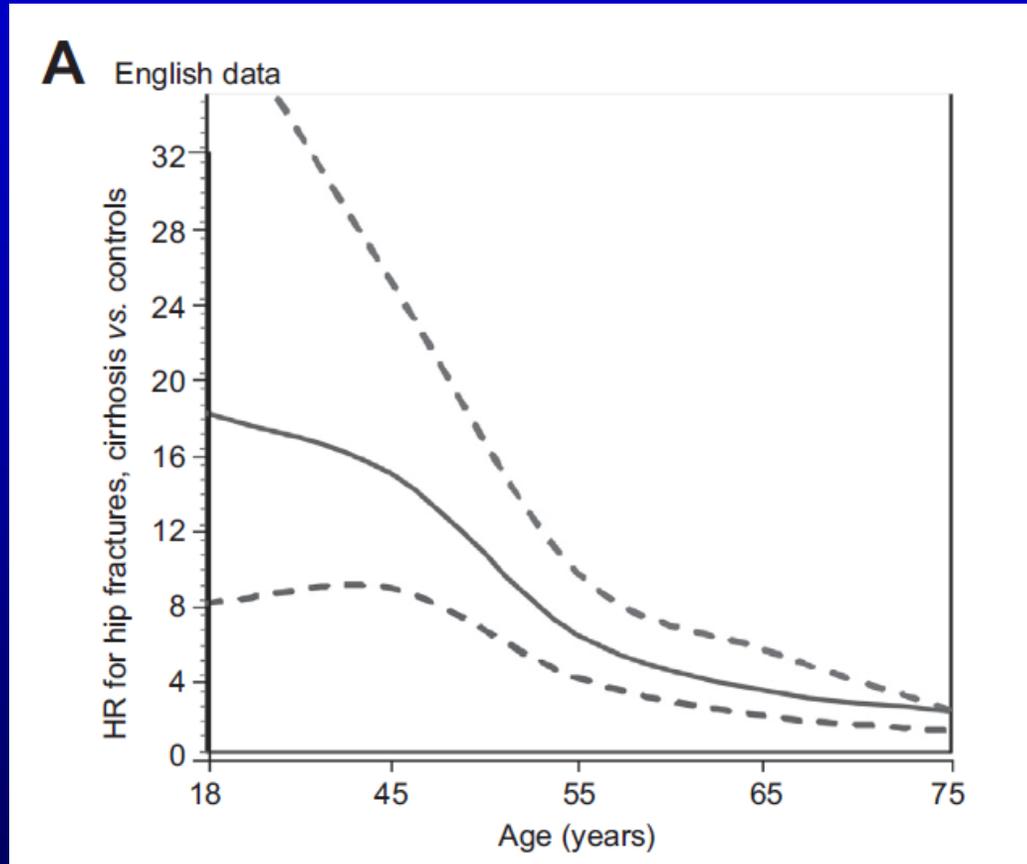

*Conclusions* Deprivation is a stronger relative predictor of hip fracture incidence in men than in women. However, given their higher hip fracture incidence, the absolute burden of deprivation on hip fractures is greater in women. Despite pub-

# Interaction of low weight over time for hip fracture among diabetics

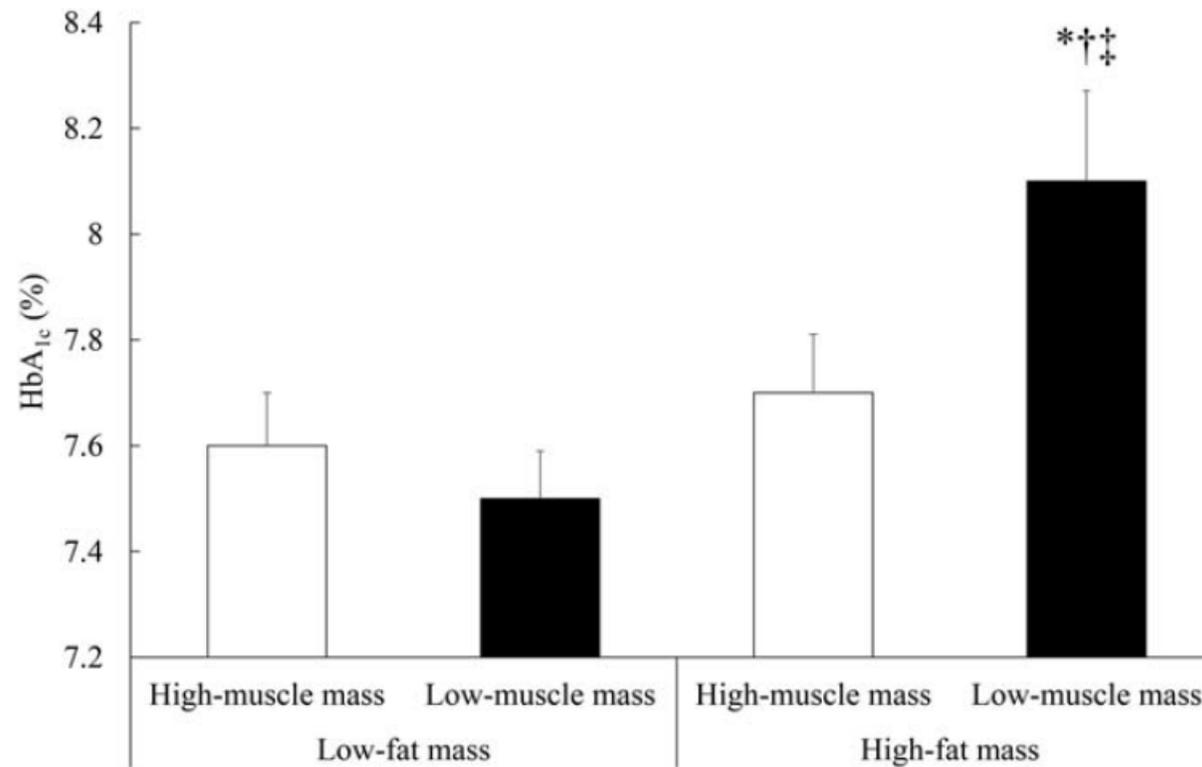

**Fig. 1** Comparisons of hip fracture risk among different BMI groups in patients with diabetes (After controlling for sex, age, urbanization of residence area, monthly salary, CCI, DCSI and weekly energy expenditure through exercise)

# Interaction of age and cirrhotic status for hip fracture

Journal of Hepatology 2018 vol. 69 | 697-704

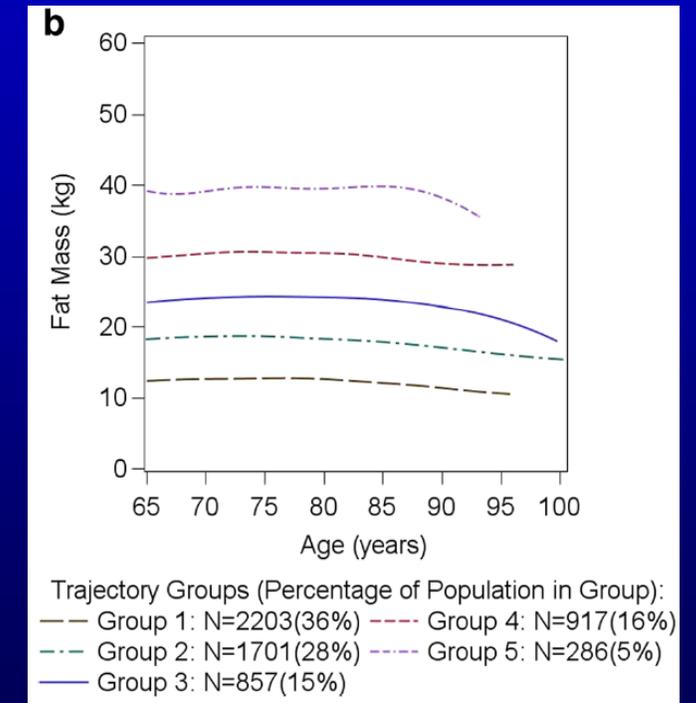

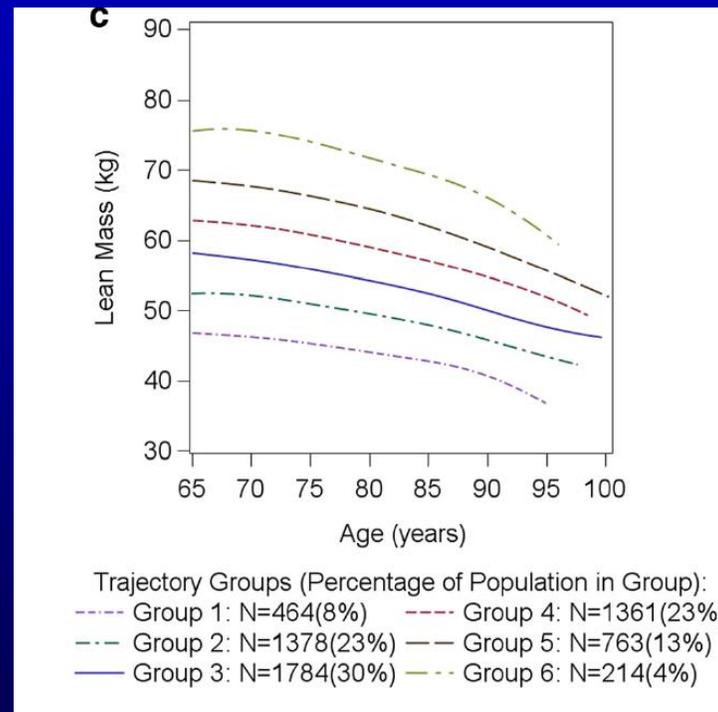

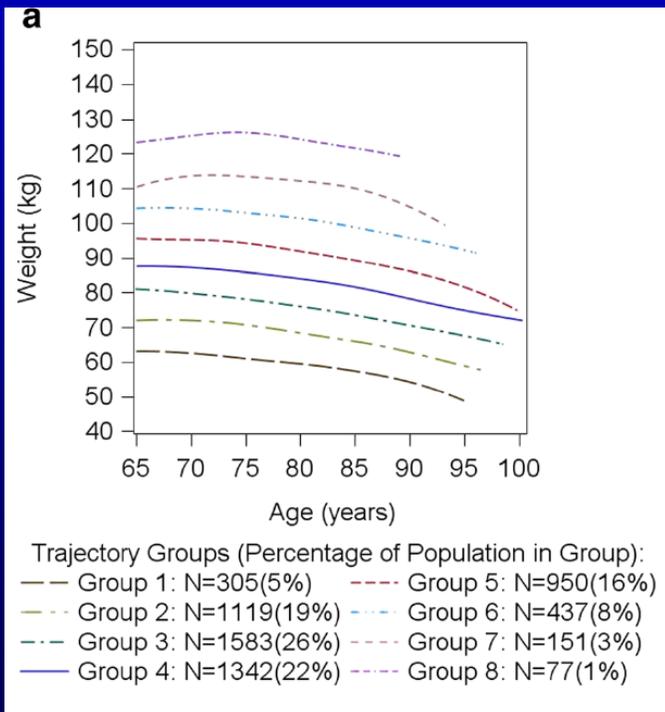

In both countries the association between cirrhosis and hip fracture rate was stronger in younger age groups (aged <45 years) than in older age ( $p$  value for interaction with age <0.001).

**Figure 1** Interaction between fat mass and muscle mass on HbA<sub>1c</sub> at baseline after adjusting for age, duration of diabetes, sex, medication, dietary protein, fat, and carbohydrate intake. Data are reported as means ± standard error of the mean. There was a significant interaction effect between fat and muscle mass ( $P = 0.009$ ). Bonferroni-adjusted pairwise comparison showed that participants with high fat and low muscle mass had higher HbA<sub>1c</sub> compared to \*high fat mass alone ( $P = 0.037$ ), †low muscle mass alone ( $P = 0.003$ ), and ‡low fat and high muscle mass ( $P = 0.007$ ).

# Interaction of weight change and age on body composition change

## Trajectories of the relationships of physical activity with body composition changes in older men: the MrOS study

**Most analytic methods can be adapted for assessment of interactions or subgroup identification.**

**Some additional methods include:**

**Stratification (a priori hypotheses versus exploratory)**

**Life course**

**Mixed models (assessment of interaction by time)**

**Classification trees**

**Major problem is power**

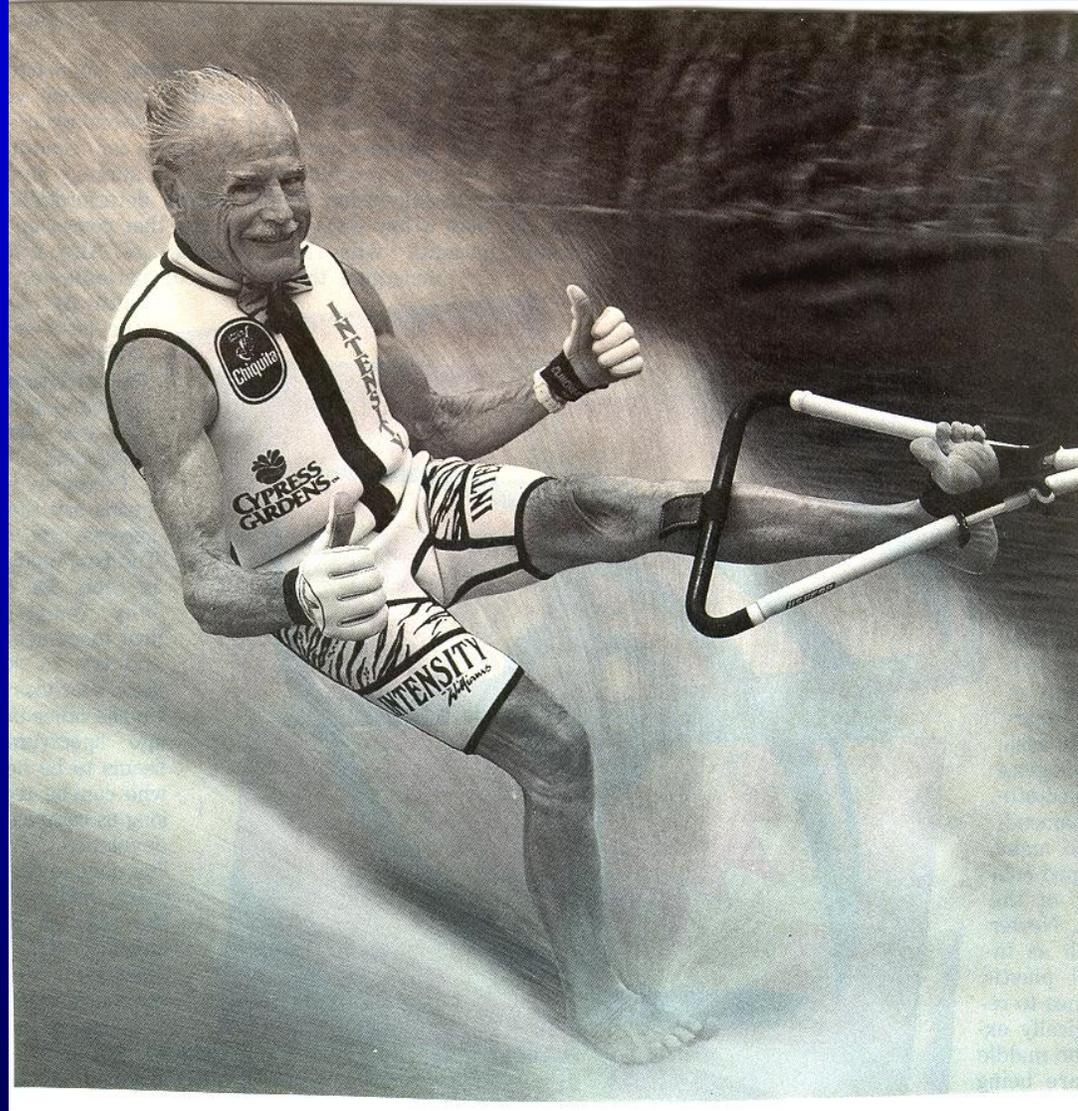

## **Knowledge Gaps:**

- **The incidence of hip and fragility fractures by health status has been explored as well as differences in recovery rates and factors contributing to the recovery or lack thereof.**
- **Relatively little has been done in assessment of subgroups in relation to biomarkers contributing to fracture.**
- **Whether there are augmented treatment strategies for selected high risk subgroups is a knowledge gap.**

**Similar gaps apply to muscle and adipose interactions.**

## **Research Opportunities:**

- **Thus far, primarily gene-environment or gene-risk factors interactions have been assessed. Other interactions bear assessment, particularly with relatively new biomarkers.**
- **Application of state-of-the-art methods for assessment of environmental interactions with bone, muscle, and adipose should be pursued.**
- **Exploration of race/ethnicity interactions may provide new insights especially comparisons in populations where naturally-occurring differences in risk factors occur including walking, smoking**

**Thank you for your attention!**

## What are interactions/effect modifications?

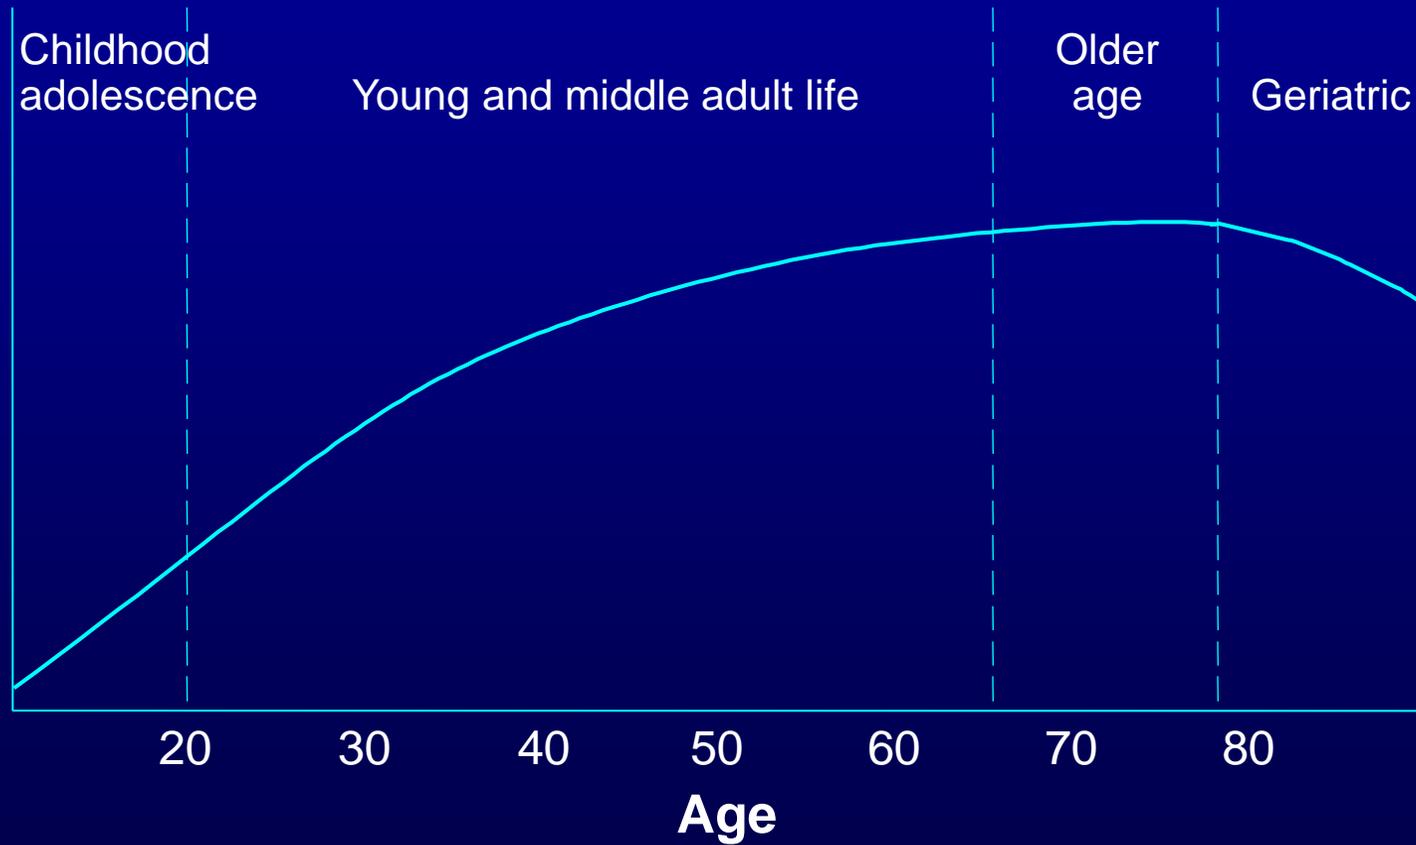

In general, the effect of one exposure may depend in some way on the presence or absence of another exposure.

**Additive** – the effect of two factors added together exceeds the effect of each individually ( $>0$ =positive additive interaction,  $<0$ =negative)

**Multiplicative** – the effect of two factors multiplied together exceeds the effect of each individually ( $>1$ =positive multiplicative interaction,  $<0$ =negative)

Any type of study, particularly genetic epidemiology

**Figure 1.** Probability of IHD by aerobic fitness and BMI in 18-year-old men with mean follow-up of 25.7 years (maximum age 62 years).

The interactive effects of aerobic fitness and BMI on risk of IHD are shown in Table 3. Low aerobic fitness was associated with increased IHD risk among men with either normal or high BMI (IRRs, 1.87 and 1.45, respectively; Table 3, right-most column). The combination of low aerobic fitness and high BMI was associated with the highest risk of IHD, which was more than 3-fold relative to the reference group of those with high aerobic fitness and normal BMI. Low aerobic fitness and high BMI had a negative interaction on the multiplicative scale ( $P_{\text{interaction}} < 0.001$ ) (i.e., their combined effect was less than the product of their separate effects), and no interaction on the additive scale ( $P_{\text{interaction}} = 0.40$ ). Figure 1 shows the probability of IHD for the 25<sup>th</sup>, 50<sup>th</sup>, and 75<sup>th</sup> percentiles of aerobic fitness across the full distribution of BMI, from the fully adjusted model.

normal BMI. Low aerobic fitness and high BMI had a negative interaction on the multiplicative scale ( $P_{\text{interaction}} < 0.001$ ) (i.e., their combined effect was less than the product of their separate effects), and no interaction on the additive scale ( $P_{\text{interaction}} = 0.40$ ). #### **FRAX Clinical Risk Factors\***

- Age
- Sex
- Weight
- Height
- Previous fracture
- Parental history of hip fracture
- Smoking status
- Glucocorticoid use
- Rheumatoid arthritis
- Secondary osteoporosis
- $\geq 3$  units of alcohol per day†
- Femoral neck BMD ( $\text{g}/\text{cm}^2$ )

*BMD = bone mineral density.*

*\* Calculator freely available at [www.shef.ac.uk/FRAX](http://www.shef.ac.uk/FRAX).*

*† The quantity of alcohol that constitutes 1 unit varies slightly by country. For FRAX, 1 unit of alcohol is equivalent to 9-10 oz of beer, 4 oz of wine, 1 oz of spirits, or 2 oz of apéritif.*

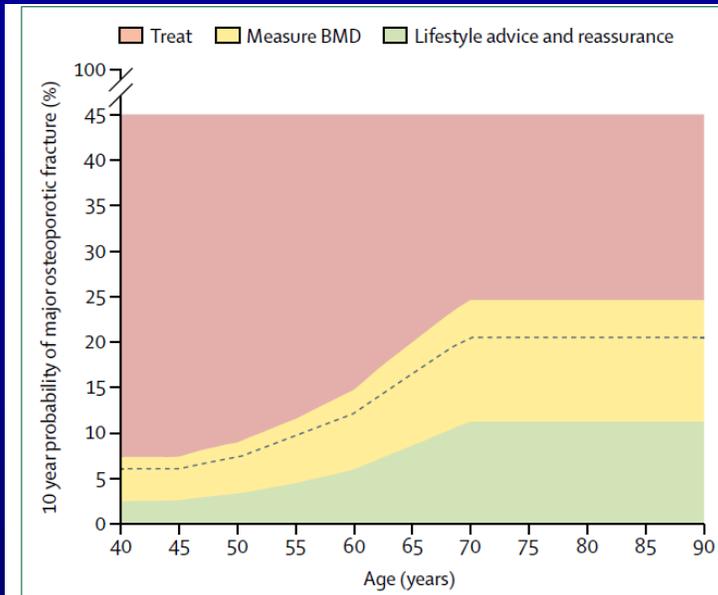

**Figure 1: Effects of antiresorptive and anabolic drugs on bone remodelling and modelling**  
 Age-related bone loss is associated with an increase in remodelling and a negative remodelling balance in individual bone remodelling units. Antiresorptive agents act predominantly by reducing remodelling rate. Anabolic agents produce their effects by increasing remodelling in combination with a positive remodelling balance, or stimulating bone modelling.

Risk factor inputs	
Fracture risk assessment tool <sup>53</sup>	Age, sex, body-mass index, previous fragility fracture, glucocorticoid use $\geq 3$ months, secondary osteoporosis, rheumatoid arthritis, parental hip fracture, current cigarette smoking, alcohol intake of $\geq 3$ units per day, femoral neck bone mineral density or T score (optional)
Garvan Fracture risk calculator <sup>54</sup>	Age, sex, fractures after age 50 years (none, 0, 1, 2, $\geq 3$ ), history of falls in the previous 12 months (none, 0, 1, 2, $\geq 3$ ), femoral neck bone mineral density or T score, weight
QFractureScores-2016 <sup>55</sup>	Age, sex, height, weight, smoking, alcohol, diabetes, previous fracture, parental osteoporosis or hip fracture, living in a nursing or care home, history of falls, dementia, cancer, asthma or COPD, cardiovascular disease, chronic liver disease, advanced chronic kidney disease, Parkinson's disease, rheumatoid arthritis, systemic lupus erythematosus, malabsorption, endocrine problems, epilepsy or anticonvulsant use, antidepressant use, steroid use, hormone replacement therapy

COPD=chronic obstructive pulmonary disease.

**Table 1: Fracture risk prediction tools with at least one independent validation cohort**

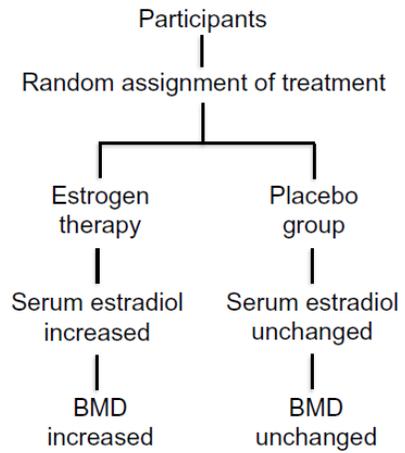

**Figure 2: UK National Osteoporosis Guidelines Group assessment and treatment thresholds**

Green denotes that an individual's risk lies below the intervention threshold—ie, pharmacological intervention is not required. Red denotes that the fracture probability is consistently above the upper assessment threshold, and pharmacological intervention is strongly recommended in most cases. Patients with fracture probabilities in the intermediate category (yellow) should be considered for BMD assessment using dual energy x-ray absorptiometry, and fracture probability should then be recomputed using the Fracture Risk Assessment Tool. Pharmacological intervention would be recommended if the recomputed fracture probability exceeds the intervention threshold (dashed line). BMD=bone mineral density.

Mendelian Randomization (MR), an approach that uses genetic variants as instrumental variables (IV) for assessing the causal effect of a risk factor on an outcome from observational data [38]. Under certain assumptions, an un-confounded estimate of the causal effect of an exposure on an outcome can be made using the observed IV-exposure and IV-outcome associations [39]. Although the assumptions underlying the validity of MR estimates are often unverifiable, a series of recent papers have proposed sensitivity analyses to test the robustness of MR results when the assumptions fail [40].

Despite the well-established role of vitamin D deficiency in bone health, current MR analyses have not provided any evidence for a genetically predicted level of 25(OH)D to be associated with neither bone mineral density (BMD) nor bone metabolism markers [41–43]. One of the largest studies, used GWAS summary statistics based on 32,965 individuals from the Genetic Factors for Osteoporosis Consortium, and 142,487 individuals from the UK Biobank, and used the previous identified 4 loci as IVs, found that genetically predicted 1 standard deviation increment of 25(OH)D was not associated with higher femoral neck BMD (change per SD = 0.02,  $p = 0.37$ ) or lumbar spine BMD (0.02,  $p = 0.49$ ), and only suggestively with estimated BMD ( $-0.03$ ,  $p = 0.02$ ), which did not pass multiple correction [42]. It is
